Precise age for the Permian-Triassic boundary in South China from high precision U-Pb geochronology and Bayesian age-depth modelling

Baresel, Björn ; Bucher, Hugo ; Brosse, Morgane ; Cordey, Fabrice ; Guodun, Kuang ; Schaltegger, Urs

Abstract: This study is based on zircon U-Pb ages of 12 volcanic ash layers and volcanogenic sandstones from two marine sections with conformable formational Permian-Triassic boundaries (PTB) in the Nanpanjiang Basin (South China). Our dates of single, thermally annealed and chemically abraded zircons bracket the PTB in Dongpan and Penglaitan and provide the basis for a first proof-of-concept study utilizing a Bayesian chronology model comparing the three sections of Dongpan, Penglaitan and the Global Stratotype Section and Point (GSSP) Meishan. Our Bayesian modeling demonstrates that the formational boundaries in Dongpan (251.938 ± 0.029 Ma), Penglaitan (251.982 ± 0.031 Ma) and Meishan (251.956 ± 0.033 Ma) are synchronous within analytical uncertainty of ca. 30 ka. It also provides quantitative evidence that the ages of the paleontologically defined boundaries, based on conodont Unitary Associations zones in Meishan and on macrofaunas in Dongpan, are identical and coincide with the age of the formational boundaries. The age model also confirms the extreme condensation around the PTB in Meishan, which distorts the projection of any stratigraphic points or intervals onto other more expanded sections by means of Bayesian age-depth models. Dongpan and Penglaitan possess significantly higher sedimentation rates and thus offer a greater potential for high resolution studies of environmental proxies and correlations around the PTB than Meishan. This study highlights the power of high-resolution radio-isotopic ages that allow a robust intercalibration of patterns of biotic changes and fluctuating environmental proxies and will help recognizing their global, regional or local significance.

Abstract. This study is based on zircon U-Pb ages of 12 volcanic ash layers and volcanogenic sandstones from two marine sections with conformable formational Permian-Triassic boundaries (PTB) in the Nanpanjiang Basin (South China). Our dates of single, thermally annealed and chemically abraded zircons bracket the PTB in Dongpan and Penglaitan and provide the basis for a first proof-of-concept study utilizing a Bayesian chronology model comparing the three sections of Dongpan, Penglaitan and the Global Stratotype Section and Point (GSSP) Meishan. Our Bayesian modeling demonstrates that the formational boundaries in Dongpan (251.938 ± 0.029 Ma), Penglaitan (251.982 ± 0.031 Ma) and Meishan (251.956 ± 0.033 Ma) are synchronous within analytical uncertainty of ca. 30 ka. It also provides quantitative evidence that the ages of the paleontologically defined boundaries, based on conodont Unitary Associations zones in Meishan and on macrofaunas in Dongpan, are identical and coincide with the age of the formational boundaries. The age model also confirms the extreme condensation around the PTB in Meishan, which distorts the projection of any stratigraphic points or intervals onto other more expanded sections by means of Bayesian age-depth models. Dongpan and Penglaitan possess significantly higher sedimentation rates and thus offer a greater potential for high resolution studies of environmental proxies and correlations around the PTB than Meishan. This study highlights the power of high-resolution radio-isotopic ages that allow a robust intercalibration of patterns of biotic changes and fluctuating environmental proxies and will help recognizing their global, regional or local significance.

1 Introduction

The Permian-Triassic boundary mass extinction (PTBME) is considered as the largest mass extinction within the Phanerozoic. About 90 % of all marine species suffered extinction (Raup, 1979; Stanley and Yang, 1994; Erwin et al., 2002; Alroy et al., 2008) and terrestrial plant communities underwent major ecological reorganisation (Hochuli et al., 2010). This major caesura in global biodiversity marked the end of the Palaeozoic faunas and the inception of the modern marine and terrestrial ecosystems (e.g., Benton, 2010; Van Valen, 1984). Several kill mechanisms has been proposed, such as global

31 regression (e.g., Erwin 1990; Yin et al., 2014), marine anoxia (e.g., Feng and Algeo, 2014), ocean acidification (e.g., Payne
32 et al., 2010) or a combination thereof. Rapid global warming (e.g., Svensen et al., 2009), high nutrient fluxes from continent
33 into oceans (Winguth and Winguth, 2012) and increased sedimentation rates (Algeo and Twitchett, 2010) also came into the
34 play, but their respective relations with the global regression near the PTB and the main extinction peak at the PTB remain
35 unclear. In spite of the rapidly growing amount of data, the detailed timing of available diversity estimates and
36 environmental proxies is still lacking, and the ultimate triggers of the PTBME remain elusive. The most likely cause derives
37 from the temporal coincidence with plume-induced massive volcanism of the Siberian Traps (e.g., Burgess and Bowring,
38 2015) that injected excessive amounts of volatiles (H_2O , CO_2 , SO_2 , H_2S) into the atmosphere. Accompanying
39 destabilization of gas hydrates (CH_4) and contact metamorphism of organic carbon-rich sediments (Retallack and Jahren,
40 2008; Svensen et al., 2009) are likely to have contributed additional volatiles into the atmosphere, thus deeply altering the
41 climate and the chemical composition of the ocean. This presumably close chronological association has led many authors to
42 support a cause-effect relationship between flood basalt volcanism and mass extinctions. Constraining the timing and
43 duration of the PTBME in a precisely and accurately quantified model that combines relative (i.e., biostratigraphy,
44 environmental changes) and sequences of absolute (zircon geochronology) ages is key to reveal the cascading causes and
45 effects connecting rapid environmental perturbations to biological responses.

46 The South China block provides a few exceptional marine successions with a continuous stratigraphic record across the PTB
47 (e.g., Yin et al., 2014). Among these is the Global Stratotype Section and Point (GSSP) in Meishan D (Yin et al., 2001),
48 where the PTB is defined by the first occurrence (FO) of the Triassic conodont *Hindeodus parvus*. Additionally, these South
49 Chinese sections reflect intense regional volcanic activity during Late Permian and Early Triassic times as manifested by
50 many intercalated zircon-bearing ash beds (Burgess et al., 2014; Galfetti et al., 2007; Lehrmann et al., 2015; Shen et al.,
51 2011). High-precision U-Pb zircon geochronology can be applied to these ash beds by assuming that the age of zircon
52 crystallization closely approximates the age of the volcanic eruption and ash deposition. Earliest U-Pb geochronological
53 studies (e.g., Bowring et al., 1998; Mundil et al., 2004; Ovtcharova et al., 2006; Shen et al., 2011) are not sufficiently precise
54 for the calibration of magmatic and biological events. Recent improvements of the U-Pb dating technique by the
55 development of the chemical abrasion-isotope dilution-thermal ionization mass spectrometry (CA-ID-TIMS; Mattinson,
56 2005), by the revision of the natural U isotopic composition (Hiess et al., 2012), by the development of data reduction
57 software (Bowring et al., 2011; McLean et al., 2011) and by the calibration of the EARTHTIME ^{202}Pb - ^{205}Pb - ^{233}U - ^{235}U tracer
58 solution (Condon et al., 2015) now provide more accurate weighted mean zircon population dates at the <80 ka level
59 (external uncertainty) for a PTB age, which allow for more precise calibration between biotic and geologic events during
60 mass extinctions and recoveries. Two of the cases benefiting from this improved technique is the highly condensed GSSP
61 defining the PTB at Meishan (Burgess et al., 2014) and the Early-Middle Triassic boundary in Monggan (Ovtcharova et al.,
62 2015).

63 The aim of this work is 1) to date the PTB in two sedimentary sections that are continuous and significantly more expanded
64 than Meishan, using the highly precise and accurate dating technique of CA-ID-TIMS, and 2) to test the age consistency

65 between the PTB as defined paleontologically in Meishan and as recognized by conformable formational boundaries in the
66 deeper water sections, Dongpan and Penglaitan. Our high-precision dates provide a future test for the synchronicity of
67 conodont biozones, chemostratigraphic correlations, and other proxies involved in the study of the PTBME. Moreover,
68 applying Bayesian age modeling (Haslett and Parnell, 2008) based on these high-precision data sets allows us to detect
69 sedimentary gaps and variations in sedimentation rate, and to directly compare other proxy data across different PTB
70 sections, inclusive of the Meishan GSSP.

71 Our data demonstrate that the PTB, as recognized in our sections by conformable boundaries between late Permian and basal
72 Triassic formations, is synchronous within analytical uncertainty of ca. 30 ka. We also show that Bayesian age models
73 produce reproducible results from different sections, even though U-Pb datasets originate from different laboratories. We
74 construct a coherent age model for the PTB in Dongpan and Penglaitan, which is also in agreement with the PTB age model
75 from Meishan (Burgess et al., 2014). These results further demonstrate that $^{206}\text{Pb}/^{238}\text{U}$ dates produced in two different
76 laboratories using the EARTHTIME tracer solution provide reproducible age information at the 0.05 % level of uncertainty.

77 2 Geological setting

78 2.1 Regional context

79 The newly investigated volcanic ash beds were sampled from two PTB sections: Dongpan in southwestern Guangxi Province
80 and Penglaitan in central Guangxi Province in South China (Fig. 1A, exact sample locations are given in Appendix A). Both
81 sections are within the Nanpanjiang Basin (Lehrmann et al., 2015), a Late Permian-Early Triassic pull-apart basin in a back
82 arc context located on the present day southern edge of the South China block. This deep-marine embayment occupied an
83 equatorial position in the Eastern Paleo-Tethys Ocean (e.g., Golonka and Ford, 2000; Lehrmann et al., 2003; Fig. 1B). The
84 basin was dominated by a mixed carbonate-siliciclastic regime during Permian and Early Triassic times and underwent a
85 major change to a flysch dominated regime in later Triassic times (e.g., Galfetti et al., 2008; Lehrmann et al., 2007). Dm-to-m
86 thick beds of mixed volcanic and clastic material as well as mm-to-cm thick volcanic ash beds are locally abundant and
87 especially well preserved in down-thrown blocks recording deep water records in low energy environments and to a lesser
88 degree, on up-thrown blocks recording shallow water to outer platform settings. Volcanic ash beds are, however, usually not
89 preserved in traction-dominated slope deposits. Genetically related volcanic rocks crop out in the south western part of the
90 basin towards Vietnam, suggesting the proximity of a volcanic arc related to the convergence between Indochina and South
91 China (Faure et al., 2016). The volcanism produced by this convergence is the most likely source of the analyzed volcanic
92 ashes (Gao et al., 2013).

93 In Dongpan and Penglaitan, the PTB is manifested by a sharp and conformable transition from the late Permian Dalong Fm.
94 (= Talung Fm.) to the basal Triassic Ziyun Fm. Late Permian rocks in these two sections are classically assigned to the
95 Dalong Fm. of Changhsingian age. However, we note that there are substantial facies differences between these two late
96 Permian records. The Dalong Fm. in Dongpan is composed of thin-bedded siliceous mudstones, numerous ash layers and

minor limestone beds (Fig. 2). This facies association is in agreement with the vast majority of reported occurrences of this formation within the South China block. The Dalong Fm. is interpreted as a basinal depositional environment with restricted circulation and an estimated water depth of 200 m to 500 m (He et al., 2007; Yin et al., 2007). In Guangxi and Guizhou, the thickness of the typical Dalong Fm. is highly variable and ranges from a couple of meters to ca. 60 m. Rocks assigned to the Dalong Fm. in Penglaitan markedly diverge from those of the typical Dalong Fm. In Penglaitan, rocks assigned to Dalong Fm. reach an unusual thickness of ca. 650 m and are lithologically much more heterogeneous, with a marked regressive episode in its middle part (Shen et al., 2007). Moreover, in Penglaitan the Dalong Fm. contains numerous volcanogenic sandstones distributed within the entire succession, a distinctive feature when compared to other sections. Only the lower part of the “Dalong Fm.” in Penglaitan can be unambiguously assigned to this formation. The middle and upper part of this section are notably shallower, showing cross bedding and ripple marks in the uppermost 30 m of the Permian, which are underlain by upper shoreface to foreshore facies deposits containing coal seams and abundant plant fossils (Shen et al., 2007). This disparate depositional setting is here interpreted as that of a fault-bounded block successively thrown down and up. Hence, Penglaitan stands in marked contrast with the homogenous deeper water facies of the typical Dalong Fm. in other sections. In Penglaitan, the topmost few meters of the Permian Dalong Fm. comprise thin bedded dark grey limestone intercalated with thick volcanogenic sandstones and thin volcanic ash beds (Fig. 3).

The conformably overlying Early Triassic rocks have been previously assigned to the Luolou Fm. in both Penglaitan and Dongpan (Feng et al., 2007; He et al., 2007; Shen et al., 2012; Zhang et al., 2006). At its type locality and elsewhere in northwestern Guangxi and southern Guizhou, the base of the Luolou Fm. is invariably represented by shallow water microbial limestone. In contrast, the onset of the Triassic at Dongpan and Penglaitan is represented by ca. 30 m of laminated black shales overlain by several hundred meters of thin bedded, mechanically laminated, medium to light grey limestone. In Dongpan, edgewise conglomerates and breccias are occasionally intercalated within the platy, thin bedded limestone unit. This succession of facies illustrates a change from basinal to slope depositional environments and is identical to that of the Ziyun Fm. at its type locality 3 km East of Ziyun County city, Guizhou Province (Guizhou Bureau of Geology and Mineral Resources, 1987). Therefore, Early Triassic rocks in Dongpan and Penglaitan are here reassigned to the Ziyun Fm., whose base is of Griesbachian age. In most sections in Guangxi and Guizhou, where latest Permian rocks are represented by the Dalong Fm., these are consistently and conformably overlain by basal black shales of the Early Triassic Ziyun Fm. or Daye Fm. (e.g., Feng et al., 2015). In these downthrown blocks, the effects of the Permian-Triassic global regression were comparatively negligible in comparison to those observed in adjacent, up-thrown blocks that recorded pronounced unconformities or condensation..

2.2 The Dongpan section

Numerous litho-, bio- and chemo-stratigraphic studies (e.g., Feng et al., 2007; He et al., 2007; Luo et al., 2008; Zhang et al., 2006) have been published on the Dongpan section during the last two decades. However, the volcanic ash beds of this continuous PTB section have never been dated. The classic lithostratigraphic subdivisions of the Dongpan section (bed 2 to

130 13; indicated on Fig. 2) (Meng et al., 2002) can easily be recognized in the field. Based on the conodont alteration index
131 (CAI), Luo et al. (2011) established that the section shows only a low to moderate thermal overprint equivalent to a maximal
132 burial temperature of 120°C. Our own estimation of the CAI of conodont elements obtained from the same beds points
133 toward values around 3, thus confirming the estimation of Luo et al. (2011).

134 Beds 2 to 5 consist of thin (dm to cm) siliceous mudstones, mudstones, minor lenticular limestone horizons and numerous
135 intercalated volcanic ash beds. These beds yield radiolarians, foraminifera (Shang et al., 2003), bivalves (Yin, 1985),
136 ammonoids (Zhao et al., 1978), brachiopods (He et al., 2005), ostracods (Yuan et al., 2007), and conodonts (Luo et al., 2008)
137 of Changhsingian age. Chinese authors have provided very detailed studies of radiolarian occurrences from the top of the
138 Dongpan section, documenting about 160 species belonging to 50 genera (Feng et al., 2007; Wu et al., 2010; Zhang et al.,
139 2006). Most of these radiolarians belong to the *Neobailiella optima* assemblage zone of Late Changhsingian age (Feng and
140 Algeo, 2014), although it is unclear if some of the Permian taxa reported from the top of the section by previous authors (i.e.
141 above bed 6, Feng et al., 2007) still belong to this assemblage or to a provisional ultimate Permian biozone (Xia et al., 2004).

142 We collected five samples with visible radiolarians (DGP-1 to DGP-5, see Fig. 2) for this study. Our goal was not to
143 duplicate the detailed faunal studies performed at Dongpan by previous authors, but essentially was to correlate these
144 previous results with our U-Pb ages using own radiolarian data. A selection of well-preserved taxa is illustrated in Appendix
145 C. We also report the occurrence of morphotypes belonging to the genus *Hegleria* which was previously reported from the
146 section but not illustrated. Our data confirm that radiolarians of the Dongpan section belong to the *Neobailiella optima*
147 assemblage zone.

148 The conodont fauna obtained from beds 3 and 5 was assigned to the *Neogondolella yini* interval zone by Luo et al. (2008).
149 *Neogondolella yini* is also a characteristic species of the UAZ1 zone, which is the oldest zone of a new high accuracy
150 zonation around the PTB constructed by means of unitary associations (Brosse et al., 2016). Bed 6 is composed of a yellow
151 fine-grained volcanic ash bed and thin-bedded siliceous mudstone. Beds 7 to 12 contain more frequent mudstone and yield a
152 diverse Permian fauna (Feng et al., 2007; He et al., 2007; Yin et al., 2007). Additionally, He et al. (2007) showed that end-
153 Permian brachiopods underwent a size reduction in the upper-most beds of the Dalong Fm., which they linked with a
154 regressive trend.

155 The sharp and conformable base (bed 13) of the Early Triassic Ziyun Fm. consists of brown-weathering black shales
156 containing a few very thin (mm-to-cm) volcanic ash beds and volcanogenic sandstones. Previous studies did not recognize
157 how recent weathering superficially altered these black shales. Bed 13 contains abundant bivalves and ammonoids of
158 Griesbachian age (Feng et al., 2007; He et al., 2007), which are also known from other sections where the equivalent black
159 shales are not weathered. Therefore, the formational boundary placed between beds 12 and 13 is reasonably well constrained
160 in terms of paleontological ages. Even in the absence of any close conodont age control, this boundary has been unanimously
161 acknowledged as the PTB in all previous contributions, thus emphasizing the significance of this formational change.

162 2.3 The Penglaitan section

163 The Penglaitan section is well known for its Guadalupian-Lopingian boundary (Capitanian-Wuchiapingian GSSP; Jin et al.,
 164 2006; Shen et al., 2007). However, the part of the section that straddles the PTB has not been the focus of any detailed
 165 published work. Shen et al. (2007) report Changhsingian *Peltichia zigzag-Paryphella* brachiopod assemblage from a
 166 volcanogenic sandstone bed at ~28 m below the PTB. In addition, *Palaeofusulina sinensis* is abundant in the uppermost
 167 limestone units of the Dalong Fm. and conodonts in the topmost part were assigned to the *Clarkina yini* Zone. A poorly
 168 preserved Permian nautiloid was recovered from the volcanogenic sandstone 1.3 m below the PTB (Fig. 3). About 0.3 m
 169 above the PTB, concretionary, thin-bedded micritic layers intercalated within the basal black shales of the Ziyun Fm. yielded
 170 one P1 element of *Hindeodus parvus* (Fig. 3). Pending the age confirmation of new paleontological data, and in full
 171 agreement with Shen et al. (2007), we place the PTB at this sharp but conformable formational boundary.

172 3 Methods

173 3.1 CA-ID-TIMS analysis

174 Sample preparation, chemical processing and U-Pb CA-ID-TIMS zircon analyses were carried out at the University of
 175 Geneva. Single zircon grain dates were produced relative to the EARTHTIME ^{202}Pb - ^{205}Pb - ^{233}U - ^{235}U tracer solution (Condon
 176 et al., 2015). All uncertainties associated with weighted mean $^{206}\text{Pb}/^{238}\text{U}$ ages are reported at the 95 % confidence level and
 177 given as $\pm x/y/z$, with x as analytical uncertainty, y including tracer calibration uncertainty, and z including ^{238}U decay
 178 constant uncertainty. The tracer calibration uncertainty (y) of 0.03 % (2σ) has to be added if the calculated dates are to be
 179 compared with other U-Pb laboratories not using the EARTHTIME tracer solution. The ^{238}U decay constant uncertainty (z)
 180 of 0.11 % (2σ) should be used if compared with other chronometers such as Ar-Ar. All $^{206}\text{Pb}/^{238}\text{U}$ single grain ages have
 181 been corrected for initial ^{230}Th - ^{238}U disequilibrium assuming $\text{Th}/\text{U}_{\text{magma}}$ of 3.00 ± 0.50 (1σ). Th-corrected $^{206}\text{Pb}/^{238}\text{U}$ dates
 182 are on average 80 ka older than the equivalent uncorrected dates when applying this correction and are presented as mean
 183 ages of selected zircon populations and their associated ± 2 -sigma uncertainties in Figs. 2 and 3, and as single grain
 184 $^{206}\text{Pb}/^{238}\text{U}$ age ranked distribution plots in Fig. 4. The full data table and analytical details are given in Appendix B.

185 3.2 Bayesian chronology

186 In this study we use Bayesian interpolation statistics to establish a probabilistic age model based on our high-precision U-Pb
 187 zircon dates of each individual ash bed and its stratigraphic position, as it is incorporated in the free Bchron R software
 188 package (Haslett and Parnell, 2008; Parnell et al., 2008) to constrain the chronological sequence and sedimentation history of
 189 the investigated sections. By assuming normal distribution of our U-Pb dates within one sample, and based on the principle
 190 of stratigraphic superposition, which requires that any stratigraphic point must be younger than any point situated below in
 191 the stratigraphic sequence, it models the age and its associated 95 % confidence interval for any depth point within the
 192 studied sedimentary sequence. The model is based on the assumption of constant sedimentation rates, which is allowed to

change several times between each dated stratigraphic point. The number of such changes is modeled by a Poisson distribution, and the size of the sedimentation rates by a gamma distribution. The strength of this approach is its flexibility that allows changes in sedimentation rate from zero (hiatus in sedimentation) to very large values (sedimentation event at high rate). In contrast to standard linear regression models, this approach leads to more realistic uncertainty estimates, with increasing uncertainty at growing stratigraphic distance from the dated layers. The model also detects and excludes outliers, which conflict with other evidence from the same sequence in order to produce a coherent and self-consistent chronology; no predefined outlier determination is required from the user. One of the drawbacks of this Bayesian approach is that a change in the sedimentation rate is assumed to occur at each dated stratigraphic position, though it is unlikely that the change in sedimentation occurs exactly at the depth of a dated bed. Another drawback is that the sedimentation parameters are shared across the whole sequence. In consequence, Bchron does not allow much opportunity for users to individually influence the chronology behaviour.

In this study we use the Bayesian Bchron model as it is part of the Bchron package (<http://cran.r-project.org/web/packages/Bchron/index.html>). This model outperforms other Bayesian age depth-models, as shown by a extensive comparison conducted on radiocarbon dates from Holocene lake sediments (Parnell et al., 2011). It provides a non-parametric chronological model according to the Compound Poisson-Gamma model defined by Haslett and Parnell (2008), requiring the weighted mean $^{206}\text{Pb}/^{238}\text{U}$ age, the stratigraphic position and the thickness of the investigated ash beds as input parameters. The technical details were given in Haslett and Parnell (2008). The Bchron model uses a Markov Chain Monte Carlo (Brooks et al., 2011) rejection algorithm which proposes model parameters and accepts or rejects them in order to produce probability distributions of dates for a given depth that match likelihood and do not violate the principle of stratigraphic superposition. In order to create an adequate number of accepted samples, the model was run for 10,000 iterations.

4 Samples

In total, 12 volcanic ash beds and volcanogenic sandstones were sampled from the Dalong Fm. of Late Permian age and from the overlying Ziyun Fm. of Early Triassic age at Dongpan and Penglaitan (see Appendix A). Most of the dated samples exhibit $^{206}\text{Pb}/^{238}\text{U}$ age dispersions that exceed the acceptable scatter from analytical uncertainty and are interpreted as reflecting magmatic residence or a combination of the latter with sedimentary recycling. Only in two cases (DGP-16, PEN-22) we find single grain analyses younger than our suggested mean age and interpret them as unresolved Pb loss since they strongly violate the stratigraphic order established by the chronology of the volcanic ash beds.

At Dongpan, six fine- to medium-grained volcanic ash beds (DGP-10, DGP-11, DGP-12, DGP-13, DGP-16 and DGP-17) in the upper-most 10 m of the Dalong Fm., one fine-grained ash bed (DGP-21) just 10 cm above the base of the Ziyun Fm., and one thin-bedded volcanogenic sandstone (DGP-18) 40 cm stratigraphically higher were collected for geochronology. At Penglaitan, the basal part of a 25 cm thick volcanogenic sandstone (PEN-6), one thin-layered volcanic ash bed (PEN-70) and the base of a 30 cm thick volcanogenic sandstone (PEN-28), all together representing the upper-most 1.1 m of the Dalong

226 Fm., were dated. A single fine-grained and extremely thin (2-3 mm) volcanic ash bed (PEN-22) was sampled 50 cm above
227 the base of the Ziyun Fm. and thus closely brackets the formational boundary. U-Pb CA-ID-TIMS geochronology following
228 procedures described above and in the appendix was applied to a number of single crystals of zircon extracted from these
229 volcanic ash beds. Trace element and Hf isotopic compositions of these dated zircons will be presented elsewhere.
230 Stratigraphic positions of volcanic ash beds at Dongpan and Penglaitan and weighted mean $^{206}\text{Pb}/^{238}\text{U}$ dates of individual
231 zircon grains for the samples below are given in Fig. 2 and Fig. 3.

232 5 Results

233 The U-Pb isotopic results are presented in Fig. 4 as $^{206}\text{Pb}/^{238}\text{U}$ age ranked plots for each individual sample, and in Table B1
234 (Appendix).

235 5.1 U-Pb age determinations from the Dongpan section

236 5.1.1 Sample DGP-10

237 This volcanic ash bed was sampled 9.7 m below the formational boundary. All ten dated zircons are concordant within
238 analytical error, where the seven youngest grains define a cluster with a weighted mean $^{206}\text{Pb}/^{238}\text{U}$ age of $252.170 \pm$
239 $0.055/0.085/0.28$ Ma (mean square of weighted deviates [MSWD] = 1.18) for the deposition of DGP-10.

240 5.1.2 Sample DGP-11

241 This volcanic ash bed was sampled 7.9 m below the formational boundary. Eleven zircon crystals were analyzed, resulting in
242 scattered $^{206}\text{Pb}/^{238}\text{U}$ dates of 251.662 ± 0.263 Ma to 252.915 ± 0.352 Ma. The six youngest zircons yield a weighted mean
243 $^{206}\text{Pb}/^{238}\text{U}$ age of $251.924 \pm 0.095/0.12/0.29$ Ma (MSWD = 1.80) that is too young with respect to the stratigraphic sequence
244 defined by over- and underlying ash beds. Therefore, we have to assume that abundant unresolved lead loss affected these
245 zircons, despite application of the same chemical abrasion procedure as for all other samples. It is worth noting that all
246 zircons from DGP-11 were almost completely dissolved after chemical abrasion and show elevated $^{206}\text{Pb}/^{238}\text{U}$ age
247 uncertainties of ~ 0.30 Ma compared to other volcanic ash beds from Dongpan.

248 5.1.3 Sample DGP-12

249 This volcanic ash bed was sampled 7.3 m below the formational boundary. The weighted mean age of $252.121 \pm$
250 $0.035/0.074/0.28$ Ma (MSWD = 1.04) is derived from eight concordant grains representing the youngest zircon population of
251 this ash bed.

252 5.1.4 Sample DGP-13

253 This volcanic ash bed was sampled 6.4 m below the formational boundary. Analyses of seven individual zircons yield a
254 statistically significant cluster with a weighted mean $^{206}\text{Pb}/^{238}\text{U}$ age of $251.101 \pm 0.037/0.075/0.28$ Ma (MSWD = 0.67)
255 representing the youngest zircon population of this ash bed.

256 5.1.5 Sample DGP-16

257 This volcanic ash bed was sampled 3.2 m below the formational boundary. Nine zircons yield a weighted mean $^{206}\text{Pb}/^{238}\text{U}$
258 age of $251.978 \pm 0.039/0.076/0.28$ Ma (MSWD = 0.66). The youngest grain shows unresolved lead loss and was discarded
259 because it strongly violates the stratigraphic superposition. Incorporating this zircon into the mean age calculation would
260 also lead to a statistically flawed MSWD of 4.80.

261 5.1.6 Sample DGP-17

262 This volcanic ash bed was sampled 2.7 m below the formational boundary. A total of 11 zircons define a weighted mean
263 $^{206}\text{Pb}/^{238}\text{U}$ age of $251.956 \pm 0.033/0.073/0.28$ Ma (MSWD = 0.96). One single zircon displays inheritance with an $^{206}\text{Pb}/^{238}\text{U}$
264 age of 252.896 ± 0.108 Ma and was consequently excluded from the weighted mean age calculation.

265 5.1.7 Sample DGP-21

266 This volcanic ash bed was sampled 0.1 m above the formational boundary. 14 zircons were dated, among which the eight
267 youngest yield a cluster with a weighted mean $^{206}\text{Pb}/^{238}\text{U}$ age of $251.953 \pm 0.038/0.075/0.28$ Ma (MSWD = 0.26). The six
268 oldest grains display an inherited component as suggested by their scattered $^{206}\text{Pb}/^{238}\text{U}$ dates ranging from 252.145 ± 0.120
269 Ma to 252.715 ± 0.084 Ma. The U-Pb data of DGP-21 was already published in a companion study (Baresel et al., in press)
270 that deals with the stratigraphic correlation of ash beds straddling the PTB in deep- and shallow-marine successions of the
271 Nanpanjiang Basin.

272 5.1.8 Sample DGP-18

273 This bed was sampled 0.5 m above the formational boundary. The re-sedimented nature of this volcanoclastic bed is reflected
274 in the $^{206}\text{Pb}/^{238}\text{U}$ zircon ages ranging from 252.559 ± 0.261 Ma to 257.274 ± 0.689 Ma. This sample was excluded from the
275 age-depth model, because it clearly violates the stratigraphic superposition.

276 5.2 U-Pb age determinations from the Penglaitan section

277 5.2.1 Sample PEN-6

278 PEN-6 comes from the base of a volcanogenic sandstone. It was sampled 1.1 m below the formational boundary. Fifteen
279 zircon grains were dated. The three youngest grains define a weighted mean $^{206}\text{Pb}/^{238}\text{U}$ age of $251.137 \pm 0.082/0.11/0.29$ Ma

(MSWD = 0.13). Because zircon dates from this bed spread over almost 2 Ma, recycling of older volcanic material via sedimentary processes appears more likely than via magmatic recycling.

5.2.2 Sample PEN-70

This volcanic ash bed was sampled 0.6 m below the formational boundary. Eighteen zircon grains were analyzed. As in the case of PEN-6, they yield a scatter of $^{206}\text{Pb}/^{238}\text{U}$ dates spanning 1.5 Ma, ranging from 251.994 ± 0.169 Ma to 253.371 ± 0.165 Ma. The weighted mean age of $252.125 \pm 0.069/0.095/0.29$ Ma (MSWD = 0.59) for the deposition of this ash bed is calculated by using the seven youngest concordant grains.

5.2.3 Sample PEN-28

This sample was taken 0.3 m below the formational boundary. It is derived from the base of a 30 cm thick volcanogenic sandstone which represents the youngest Permian bed in Penglaitan. Analyses of seven zircon grains yield a cluster with a weighted mean $^{206}\text{Pb}/^{238}\text{U}$ age of $252.062 \pm 0.043/0.078/0.28$ Ma (MSWD = 0.49), reflecting the last crystallization phase of this zircon population. Six older grains ranging from 252.364 ± 0.156 Ma to 253.090 ± 0.375 Ma indicate either magmatic or sedimentary recycling. The U-Pb data of PEN-28 was already published in Baresel et al. (in press).

5.2.4 Sample PEN-22

This 2 mm thick volcanic ash bed was sampled 0.5 m above the formational boundary. Eight zircons yield a weighted mean $^{206}\text{Pb}/^{238}\text{U}$ age of $251.907 \pm 0.033/0.073/0.28$ Ma (MSWD = 0.10). One zircon grain shows a significantly younger age suggesting lead loss. Two slightly older grains reflect noticeable pre-eruptive crystallization. Incorporation of these grains into the weighted mean calculation would lead to an excessive MSWD of 3.6 and 1.9, respectively.

However, we noticed that some volcanic ash beds and volcanogenic sandstones in these sections show a large age dispersion of up to 2 Ma, incompatible with recycling of zircon that previously crystallized within the same magmatic system and became recycled into later melt batches, leading to few 100 ka dispersion of dates (e.g., Broderick et al., 2015; Samperton et al., 2015), but pointing to sedimentary reworking. The U-Pb data of PEN-22 was already published in Baresel et al. (in press).

5.3 Age-depth models

Figure 5 shows a comparison of three different age-depth models based on linear interpolation, cubic spline interpolation and Bayesian statistics, each applied to exactly the same U-Pb dataset of Dongpan (Fig. 5a) and Penglaitan (Fig. 5b). It is visible that, the Bayesian Bchron model produces a slightly increased uncertainty of the model age with increasing distance from the stratigraphic position of a U-Pb dated sample (as discussed in the Methods' section). Due to the well constrained U-Pb dates of Dongpan and Penglaitan, all three age-depth models predict (within uncertainty) similar ages for the PTB in Dongpan (Fig. 5a) and Penglaitan (Fig. 5b). Given that the Bayesian Bchron model evaluates the age probability distribution

of each U-Pb date with respect to the other dates of the sequence, it provides a more robust and better constrained chronology, which even results in smaller uncertainties of the predicted model dates compared to the standard linear regression models (as indicated by the smaller uncertainty of the Bchron model age for the PTB in Dongpan and Penglaitan). In contrast to the other two models, the Bayesian Bchron model can identify U-Pb dates that violate the principle of stratigraphic superposition, as shown for the Dongpan ash beds DGP-11 (outlier probability of 67 %) and DGP-18 (outlier probability of 100 %). Including them into the age-depth chronology of Dongpan results in unrealistic negative sedimentation rates, as reflected by the linear and cubic interpolation models for the interval between DGP-11 and DGP-12, and for the interval between DGP-21 and DGP-18 (Fig. 5a).

The aim for applying Bayesian age modelling to the dated volcanogenic beds from these two sections was to obtain an age model for the PTB. The age-depth models yield ages of 251.938 ± 0.029 Ma (Dongpan; Fig. 2; Fig. 5a) and of 251.982 ± 0.031 Ma (Penglaitan; Fig. 3; Fig. 5b) for the lithological boundary between the Dalong and Ziyun Fm. in both sections. These two ages overlap within uncertainties and thus demonstrate the synchronicity of the PTB in the two sections. Making the reasonable assumption of absence of significant gaps in these two sections, the new U-Pb dates can be used to infer sedimentation rates. The age-depth model of Dongpan suggests increased sedimentation rates in the upper-most part of the Dalong Fm. from bed 6 (DGP-17) upwards. Below bed 6, calculated sedimentation rates appear to be relatively constant with 3.6 ± 1.2 cm ka^{-1} , but above bed 6 they jump to 6.0 ± 2.4 cm ka^{-1} . In Penglaitan, the sedimentation rate of the upper-most Dalong Fm. and basal-most Ziyun Fm. is significantly lower than in Dongpan with 0.7 ± 0.3 cm ka^{-1} . Previously published U-Pb zircon geochronology from Penglaitan (Shen et al., 2011), including a weighted mean date of 252.16 ± 0.09 Ma from a volcanogenic sandstone at 26.7 m below the PTB, was not considered in our age model, since substantial improvements in the analytical protocol hamper comparing these dates with our U-Pb results.

6 Comparison of the Dongpan and Penglaitan sections with Meishan GSSP Results

6.1 The change of the PTB age through analytical improvement of U-Pb dating

The first geochronological studies in the GSSP Meishan D have been carried out on bed 25, immediately underlying the PTB, by U-Pb sensitive high-resolution ion microprobe (SHRIMP) analysis of zircons yielding a $^{206}\text{Pb}/^{238}\text{U}$ age of 251.2 ± 3.4 Ma (Claoué-Long et al., 1991) and by $^{40}\text{Ar}/^{39}\text{Ar}$ dating of sanidine at 249.91 ± 0.15 Ma (Renne et al., 1995). However, these dates are either not sufficiently precise to allow calibrating magmatic and biological timescales at resolution adequate for both groups of processes, or are biased by a systematic age offset between the U-Pb and Ar-Ar systems of ~ 1.0 % (Schoene et al., 2006). In order to properly compare the two systems, all older $^{40}\text{Ar}/^{39}\text{Ar}$ data have to be corrected for the revised age of the standard Fish Canyon sanidine of 28.201 ± 0.046 Ma (Kuiper et al., 2008) and the decay constant uncertainty has to be added to U-Pb and Ar-Ar ages which would drastically expand the $^{40}\text{Ar}/^{39}\text{Ar}$ age error and recalculate the $^{40}\text{Ar}/^{39}\text{Ar}$ age of Renne et al. (1995) to 252.1 ± 1.6 Ma. In a first detailed ID-TIMS study, U-Pb ages of mechanically abraded zircons were published by Bowring et al. (1998) for six volcanic ash beds at Meishan, placing the PTB at $251.4 \pm$

0.3 Ma. Though much more precise than former studies, these ages are mainly based on multi-grain zircon analyses. That this approach might disguise complexity of zircon population ages, as pervasive lead loss and inheritance, was shown by Mundil et al. (2001) by confining data selection to single-crystal analyses of the same horizons. In a second attempt, driven by further improvements of the U-Pb ID-TIMS technique (e.g., chemical abrasion of zircon grains by hydrofluoric acid exposure to remove zircon domains with lead loss; reduced procedural common Pb blanks), the PTB extinction horizon in Meishan and Shangsi (China) was dated at 252.6 ± 0.2 Ma by Mundil et al. (2004). Unlike previous studies, Shen et al. (2011) dated larger number of zircon grains per ash bed in order to overcome inheritance, magmatic residence, and lead loss phenomena of zircon population ages. They determined the duration of the PTB extinction interval (bed 25 to bed 28 in Meishan) at 200 ± 100 k.y. starting at 252.28 ± 0.08 Ma in bed 25 together with a sharp negative $\delta^{13}\text{C}$ excursion. By using the same mineral separates from identical ash beds as in Shen et al. (2011), the extinction period at Meishan was determined by Burgess et al. (2014) between 251.941 ± 0.037 Ma (bed 25) and 251.880 ± 0.031 Ma (bed 28). The differences in age and precision compared to Shen et al. (2011) reflect significant progress of the EARTHTIME community in data acquisition and reduction such as refined tracer calibration, new error propagation algorithms, and the development of the EARTHTIME ^{202}Pb - ^{205}Pb - ^{233}U - ^{235}U tracer solution.

Figure 6 illustrates the three Bayesian age-depth models based on our U-Pb dates from Dongpan and Penglaitan compared to the latest generation of U-Pb ages from Meishan GSSP (Burgess et al. 2014). Such a comparison is possible because all the dates from these three sections were obtained with the same analytical procedures, including identical data reduction procedures, error propagation and Th correction, thus leading to closely comparable precision and accuracy of the ages. This tight temporal framework allows us to perform a quantitative comparison of the Dongpan, Penglaitan and Meishan sections in terms of lithostratigraphy, biostratigraphy and chemostratigraphy via the Bayesian statistics.

6.2 Comparison of lithostratigraphy

All three interpolated ages of the formational boundary in Dongpan (251.938 ± 0.029 Ma), Penglaitan (251.982 ± 0.031 Ma) and Meishan (251.956 ± 0.033 Ma) are in agreement within errors (Fig. 6). They support the synchronicity of the conformable boundary between the Dalong Fm. and the Ziyun Fm. in Dongpan and Penglaitan, and also demonstrate their temporal coincidence with the conformable boundary in Meishan between the Changhsing Fm. and Yinkeng Fm. The age model also confirms the extreme condensation around the PTB in Meishan, with a maximal sedimentation rate of 0.4 cm ka^{-1} as reported by Burgess et al. (2014) for the 26 cm thick interval bracketed by beds 25 and 28. In this respect, Dongpan and Penglaitan offer a greater potential for higher resolution studies of environmental proxies around the PTB with maximal sedimentation rates for the same interval of 8.4 cm ka^{-1} and 1.0 cm ka^{-1} , respectively. The increased sedimentation rate above bed 6 in Dongpan is in agreement with the previously inferred sedimentary fluxes deduced from elemental chemical analyses (Shen et al., 2012). From bed 7 upward, He et al. (2007) showed a clear increase of Al_2O_3 and TiO_2 indicating increased fluxes of terrestrial input into this trough. The accompanying size reduction of brachiopods (He et al., 2007) led them to infer a regressive trend in the upper part of the Dongpan section. The ecological consequences of any regressive trend or increased

375 elastic input might conceivably impact the diversity of marine species but distinguishing between increased fluxes and
376 regression remains difficult because both causes may have converging consequences.

377 6.3 Comparison of biostratigraphy

378 The PTB is defined by the FO of *H. parvus* in the GSSP Meishan D in bed 27c. This definition is complicated by the
379 suggested existence of a hardground within bed 27, which is at the position of the previously defined PTB (Chen et al.,
380 2009). Others have suggested that the FO of *H. parvus* at Meishan is not the timing of the true evolutionary origination of
381 this species (Jiang et al., 2011; Yuan et al., 2015). In Meishan, the FO of *H. parvus* in bed 27c is interpolated at $251.892 \pm$
382 0.045 Ma (Fig. 6) and is located 21 cm above the formational boundary which occurs between beds 24 and 25. Temporally
383 coincident, the FO of *H. parvus* in Penglaitan is interpolated at 251.929 ± 0.032 Ma (Fig. 6) and is located 33 cm above the
384 formational boundary. With respect to formational boundaries, the higher stratigraphic position of the FO of *H. parvus* in
385 Penglaitan than in Meishan is to be expected because of the higher sedimentation rate. However, in Meishan *H. parvus* first
386 occurs 64 ± 56 k.y. after the formational boundary and in Penglaitan after 53 ± 46 k.y., indicating perfect synchronicity
387 within our temporal resolution. In Dongpan, the lack of conodont bearing beds around the PTB hampers testing the
388 synchronicity of the FO of *H. parvus* between Dongpan and the two other sections.

389 Brosse et al. (2016) established a new and robust conodont zonation based on unitary associations around the PTB in South
390 China that includes the Meishan GSSP. This zonation contains six Unitary Association Zones (UAZ), with the PTB falling
391 into the separation interval between UAZ2 (bed 25) and UAZ3 (bed 27a-d). This new zonation also places the UAZ-based
392 PTB in Meishan closer to the conformable boundary between the Changhsing and the Yinkeng formations than the FO of *H.*
393 *parvus* (bed 27c) does. Available conodont data from Meishan allow the assignment of bed 24a-e to UAZ1 (UAZ1 might
394 reach further down as indicated by a dashed line in Fig. 6), bed 25 to UAZ2, bed 27a-d to UAZ3 and bed 28 to UAZ4
395 (Brosse et al., 2016). The stratigraphic thickness comprised between the base of UAZ1 and the top of UAZ4, amounts to
396 1.22 m. By using the three section age-depth models, we attempted to project the respective thickness corresponding to the
397 UAZ1-UAZ4 interval in Meishan onto the two other sections. This projection resulted into a pronounced, artificial
398 lengthening of UAZs in Dongpan and Penglaitan. UAZ1 is the penultimate Permian conodont UAZ in Meishan (Brosse et
399 al., 2016). When projected onto the age-depth models of Dongpan and Penglaitan, this UAZ1 is artificially expanded and
400 even crosses the PTB in Penglaitan (Fig. 6). In Penglaitan, the last Permian UAZ2 projects correctly above UAZ1 without
401 overlap but is completely within the Triassic. The cause of these contradictions stems from the irreconcilable conjunction of
402 i) extreme condensation in Meishan, ii) high evolutionary rates of conodonts, and iii) the ca. 30 ka precision of the last
403 generation of U-Pb dates.

404 In Dongpan, the onset of a protracted radiolarian diversity decline in bed 5 reported by Feng and Algeo (2014) is here
405 interpolated at 251.990 ± 0.027 Ma, occurring 52 ± 40 k.y. before the formational boundary (Fig. 2). Excess SiO_2 values of
406 this bed (Shen et al., 2012) suggest a genuine diversity pattern at the local scale, which seems to be unrelated to any

substantial change or trend in the local redox conditions (as shown by Co/Al, Cr/Al, Cu/Al and V/Al measurements of He et al., 2007).

6.4 Comparison of chemostratigraphy

Organic carbon isotope chemostratigraphy of Dongpan (Fig. 7) extending from the Permian bed 5 to the Triassic bed 13 was provided by Zhang et al. (2006) and for Meishan (Fig. 7) extending from the Permian bed 24 to the Triassic bed 29 by Cao et al. (2002). The correlation of these $\delta^{13}\text{C}_{\text{org}}$ records by Zhang et al. (2006), based on the occurrence of ash beds in both sections, is largely over-interpreted. With the exception of a short negative excursion followed by a more prominent positive excursion between beds 9 and 11, the Permian part of the $\delta^{13}\text{C}_{\text{org}}$ record in Dongpan is relatively stable and oscillates between -28 ‰ and -27 ‰. With the exception of a negative excursion culminating in beds 25 and 26, the Permian part of the $\delta^{13}\text{C}_{\text{org}}$ record in Meishan shows a sustained positive trend from -30 ‰ to -26 ‰. The basal Triassic part of these two records is also incompatible in that they display opposed trends. With the possible exception of the Xinmin section (Shen et al., 2013a), the $\delta^{13}\text{C}_{\text{org}}$ record of Dongpan does not correlate with that of any other South Chinese section, but even Xinmin shows a ~3 ‰ offset of the base trend in comparison to Dongpan. However, we note that in Meishan an abrupt decline in $\delta^{13}\text{C}_{\text{carb}}$ occurs in bed 24e at 251.950 ± 0.042 Ma (Burgess et al., 2014) and slightly above in bed 26 in $\delta^{13}\text{C}_{\text{org}}$ at 251.939 ± 0.032 Ma, which is temporally coincident with the main negative $\delta^{13}\text{C}_{\text{org}}$ excursion in bed 9 in Dongpan at 251.954 ± 0.027 Ma. The second smaller negative $\delta^{13}\text{C}_{\text{org}}$ excursion at the PTB in Dongpan at 251.942 ± 0.028 Ma and in Meishan at 251.892 ± 0.045 Ma cannot be distinguished within uncertainty from the main excursion, which hampers the correlation of the $\delta^{13}\text{C}_{\text{org}}$ records based on U-Pb ages. However, interpreting organic carbon records requires the simultaneous analysis of palynofacies, which are not documented in Dongpan. Shen et al. (2012) also showed that the total organic carbon (TOC) never exceeds 0.2 %, thus indicating a generally poor preservation of the organic matter in this section. As shown by Shen et al. (2012), this preservation bias is further supported by coincident peaks in both terrestrial (spore and pollens) and marine (algae and acritarchs) organic material (see Fig. 7). This uneven preservation of the organic matter further hampers the understanding of the $\delta^{13}\text{C}_{\text{org}}$ signal in Dongpan. More generally, the consistency and lateral reproducibility of the Late Permian carbonate and organic carbon isotope records in South China remain equivocal (e.g., Shen et al., 2013b). These records are probably influenced by the local graben and horst paleotopography that hampered efficient circulation of water masses with the open ocean, thus reflecting more local than global changes.

7 Conclusions

- The comparison of our high-precision U-Pb zircon data from Dongpan and Penglaitan sections in South China with the data of Burgess et al. (2014) from Meishan D GSSP provides convincing evidence that dates elaborated through the use of the EARTHTIME ^{202}Pb - ^{205}Pb - ^{233}U - ^{235}U tracer solution are comparable at the 0.05 % level or better even if coming from different laboratories. This fact underlines a substantially increased accuracy and precision of U-Pb ID-TIMS dating, now capable to elucidate environmental change and biotic response on a decamillennial scale.

- 439 • Applying Bayesian age modelling to sections with such high-precision time information allows to compare disparate
- 440 information from different sections, quantitatively. Along with the work of Ovtcharova et al. (2015) at the Early-Middle
- 441 Triassic boundary, these are the two first proof-of-concept studies adopting age-depth modelling to compare coeval sections
- 442 with different fossil contents, different facies and disparate sedimentation rates at highest temporal resolution. We anticipate
- 443 that this approach will need to become the future standard in the assessment of the Geologic Time Scale.
- 444 • Bchron age-depth models demonstrate synchronicity of the conformable lithological boundaries in Dongpan, Penglaitan,
- 445 and Meishan. These results highlight the temporal reliability of the environmental changes as expressed by formational
- 446 boundaries in platform-slope and deeper water basinal sections.
- 447 • The reappraisal of the PTB in South China based on conodont Unitary Associations zones (Brosse et al., 2016) coincides
- 448 with the PTB age of Dongpan, and favours this characterization of the PTB over the classical definition by the FO of *H.*
- 449 *parvus*.
- 450 • The higher sedimentation rates of Dongpan and Penglaitan provide a much better prospect for the high-resolution study of
- 451 environmental proxies around the PTB than the condensed GSSP section in Meishan. Our age-depth models also reveal that
- 452 the combination of condensed deposition with high evolutionary rates of conodonts and the ~30 ka resolution of the last
- 453 generation of U-Pb ages makes it impossible to project stratigraphic data points or intervals of Meishan onto expanded PTB
- 454 sections without distortions. This intrinsic problem of the Meishan GSSP section should stimulate the search of alternative
- 455 sections with more expanded records.
- 456 • The seemingly erratic Late Permian carbon isotope record in South China does not allow laterally reproducible inter-
- 457 calibration with the newly obtained U-Pb dates. This stands in sharp contrast with the Early Triassic carbon isotope record
- 458 which is of global significance (e.g., Galfetti et al., 2007).

459 Acknowledgements

460 The authors acknowledge financial support by the Swiss NSF through projects 200020_137630 (to U.S.) and

461 200021_135446 (to H.B.). Aymon Baud (Lausanne) is thanked for its support in the field. Tom Algeo (Cincinnati) and Shen

462 Shuzhong (Nanjing) are thanked for insightful discussions and for providing Excel tables of carbon isotopic data from

463 published sections. A special thanks goes to technical and scientific members of the Geneva and Zürich research groups,

464 who helped during all stages of this study.

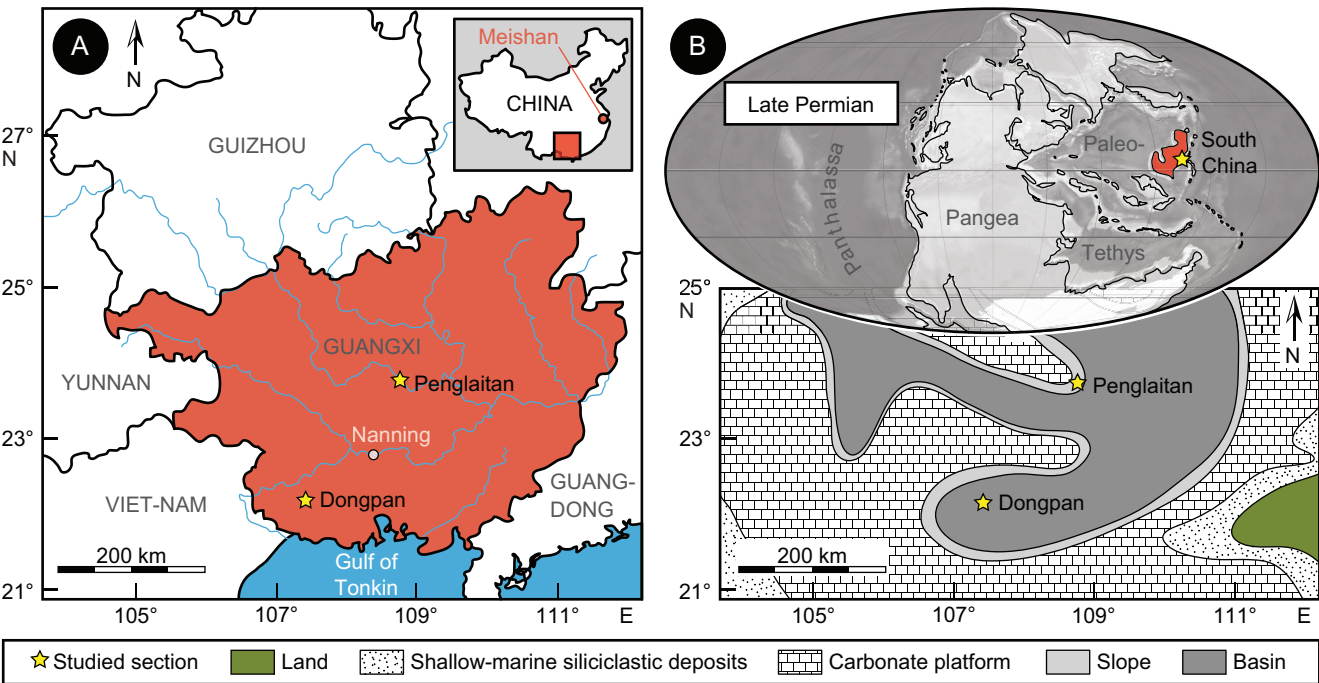

Fig. 1. A) Locality map showing the position of the studied sections in the Guangxi province, China. B) Late Permian paleogeographic reconstruction after Ziegler et al. (1997), showing the location of the South China Block in the peri-Gondwana region. Beneath the paleogeographic map of the Nanpanjiang Basin in South China indicating the position of the Dongpan and Penglaitan section during Late Permian times (base map modified after Wang and Jin, 2000).

Fig. 2. Stratigraphy and geochronology for the Dongpan section from late Changhsingian to Griesbachian showing weighted mean $^{206}\text{Pb}/^{238}\text{U}$ dates of the volcanic ash beds and volcanogenic sandstones. U-Pb data of DGP-21 is taken from Baresel et al. (in press). Investigated radiolarian samples (DGP-1 to DGP-5) are shown in their stratigraphic positions. The Bayesian Bchron age-depth model is presented with its median (middle grey line) and its associated 95 % confidence interval (grey area). Radioisotopic dates together with their uncertainty (red horizontal bars) are presented as $^{206}\text{Pb}/^{238}\text{U}$ weighted mean dates of the dated volcanic ash beds in their stratigraphic positions. Predicted dates for the onset of the radiolarian decline (RD) and the Permian-Triassic Boundary (PTB) are calculated with their associated uncertainty using the Bayesian Bchron age-depth model assuming stratigraphic superposition.

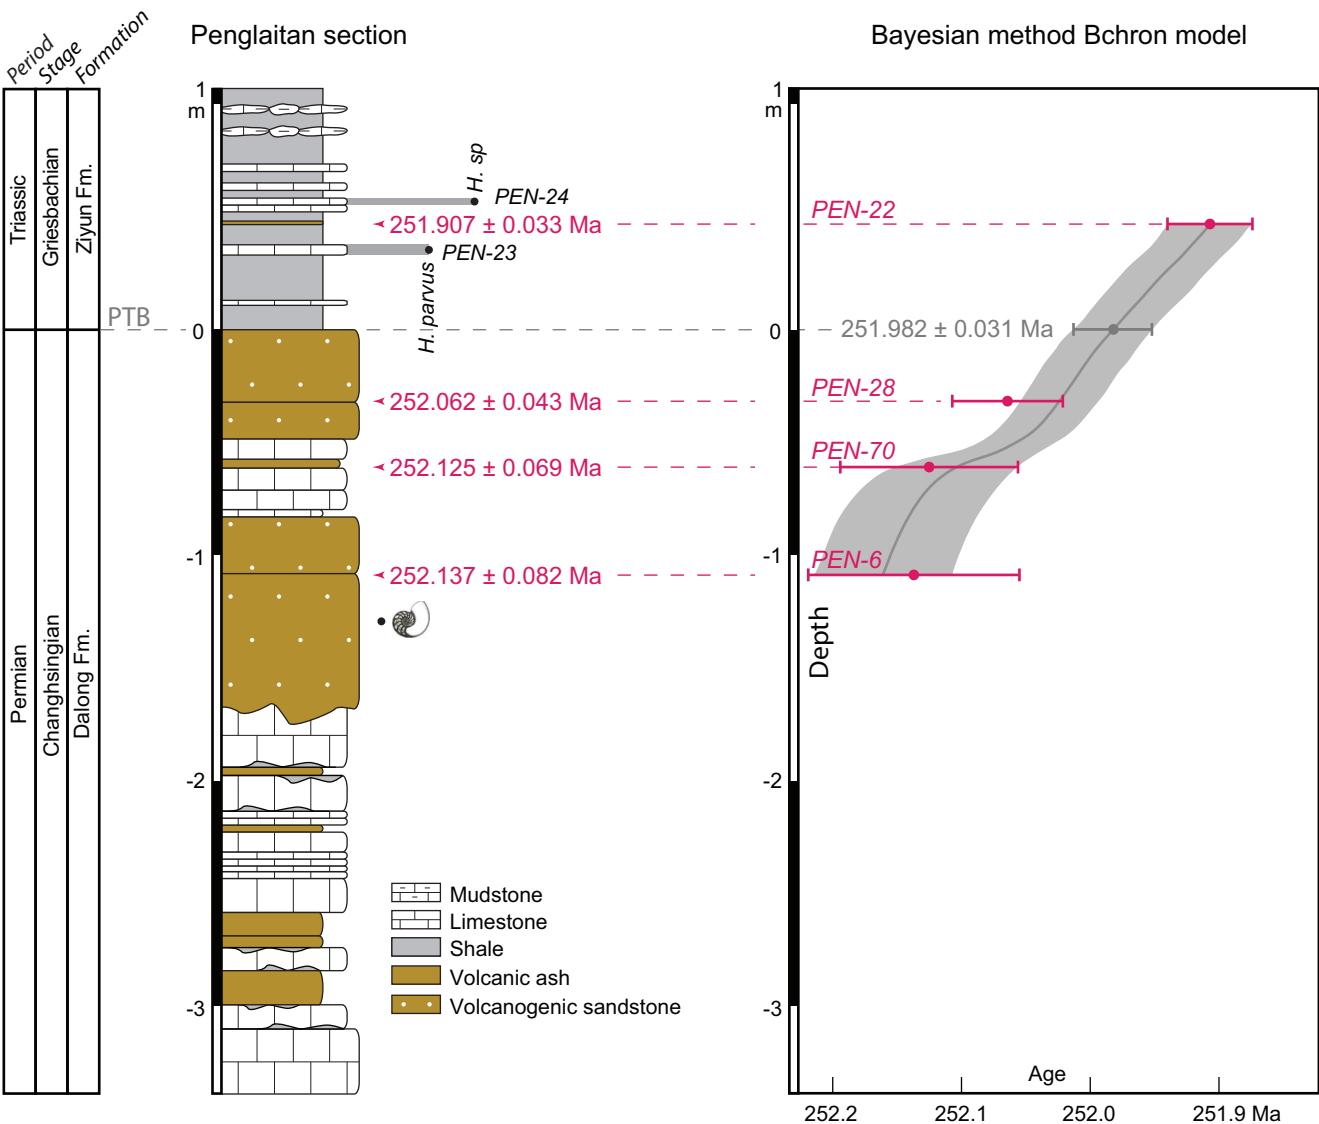

Fig. 3. Stratigraphy and geochronology for the Penglaitan section from late Changhsingian to Griesbachian showing weighted mean $^{206}\text{Pb}/^{238}\text{U}$ dates of the volcanic ash beds and volcanogenic sandstones. U-Pb data of PEN-28 and PEN-22 are taken from Baresel et al. (in press). Investigated conodont samples (PEN-23 and PEN-24) and first occurrence of Triassic conodonts are shown in their stratigraphic positions. A poorly preserved Permian nautiloid is indicated in its stratigraphic position ca. 1.3 m below the Permian-Triassic Boundary (PTB). The Bayesian Bchron age-depth model is presented with its median (middle grey line) and its associated 95 % confidence interval (grey area). Radioisotopic dates together with their uncertainty (red horizontal bars) are presented as $^{206}\text{Pb}/^{238}\text{U}$ weighted mean dates of the dated volcanic ash beds in their stratigraphic positions. Predicted dates for the PTB are calculated with their associated uncertainty using the Bayesian Bchron age-depth model assuming stratigraphic superposition.

Fig. 4. Single-grain zircon analysis and $^{206}\text{Pb}/^{238}\text{U}$ weighted mean dates for Dongpan and Penglaitan volcanic ash beds and volcanogenic sandstones. U-Pb data of DGP-21, PEN-28 and PEN-22 are taken from Baresel et al. (in press). Each horizontal bar represents a single zircon grain analysis including its 2σ analytical (internal) uncertainty whereas grey bars are not included in the weighted mean calculation. Vertical lines represent the weighted mean age, with the associated 2σ uncertainty (in grey). Uncertainty of the weighted mean dates is reported as 2σ internal, 2σ external uncertainty including tracer calibration and 2σ external uncertainty including ^{238}U decay constant uncertainty; MSWD - mean square of weighted deviates.

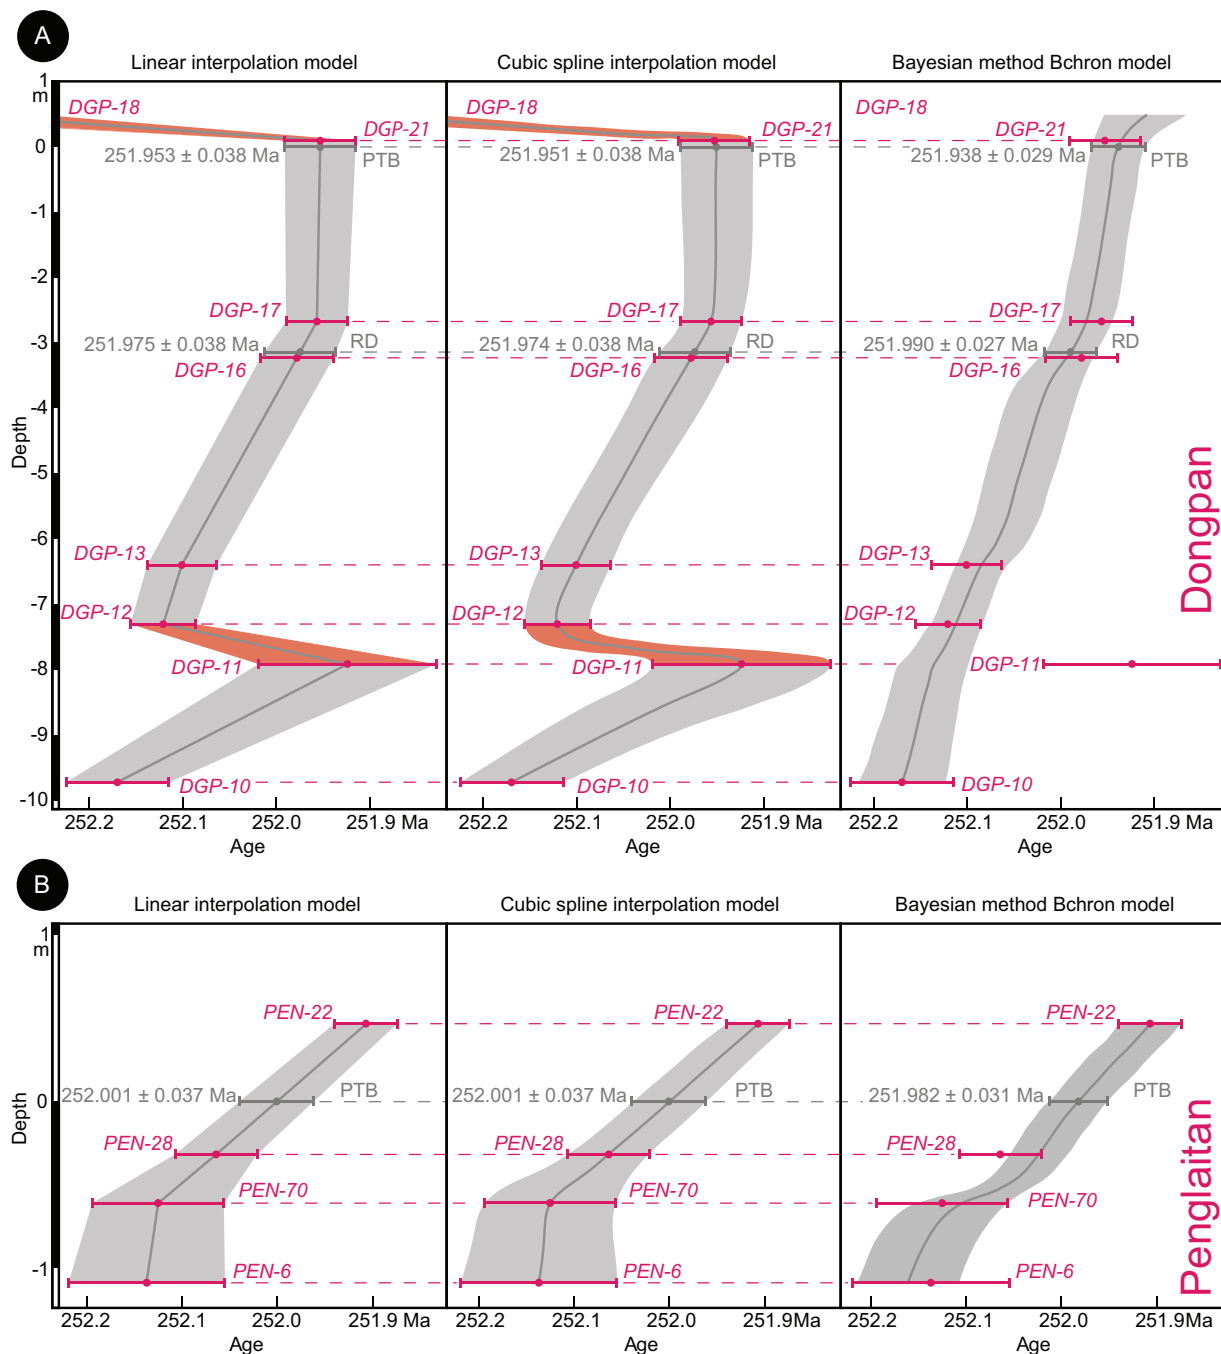

Fig. 5. Comparison of the different age-depth-models based on linear interpolation, cubic spline fit and Bayesian statistics for A) Dongpan and B) Penglaitan. Each age-depth model is presented with its median (middle grey line) and its associated 95 % confidence interval (grey area). Radioisotopic dates, used in the age-depth-models, together with their uncertainty (red horizontal bars) are presented as $^{206}\text{Pb}/^{238}\text{U}$ weighted mean dates of the Dongpan and Penglaitan volcanic ash beds and volcanogenic sandstones in their stratigraphic positions. U-Pb data of DGP-21, PEN-28 and PEN-22 are taken from Baresel et al. (in press). Predicted dates (grey horizontal bars) for the onset of the radiolarian decline (RD) and the Permian-Triassic Boundary (PTB) in Dongpan and Penglaitan are calculated with their associated uncertainty using the different age-depth models.

Fig. 6. Comparison of Bayesian Bechron age models for Dongpan, Penglaitan and the GSSP section Meishan D. Predicted dates together with their uncertainty for the lithological boundaries and the first occurrence of the conodont *Hindeodus parvus* at Dongpan and Penglaitan are calculated using U-Pb ages of this study and of Baresel et al. (in press), and the U-Pb ages of Burgess et al. (2014) for Meishan. The durations of the conodont UAZ1 and UAZ2 (Brosse et al., 2016) are inferred from the Bechron age model of Meishan and projected to the model of Dongpan and Penglaitan, respectively.

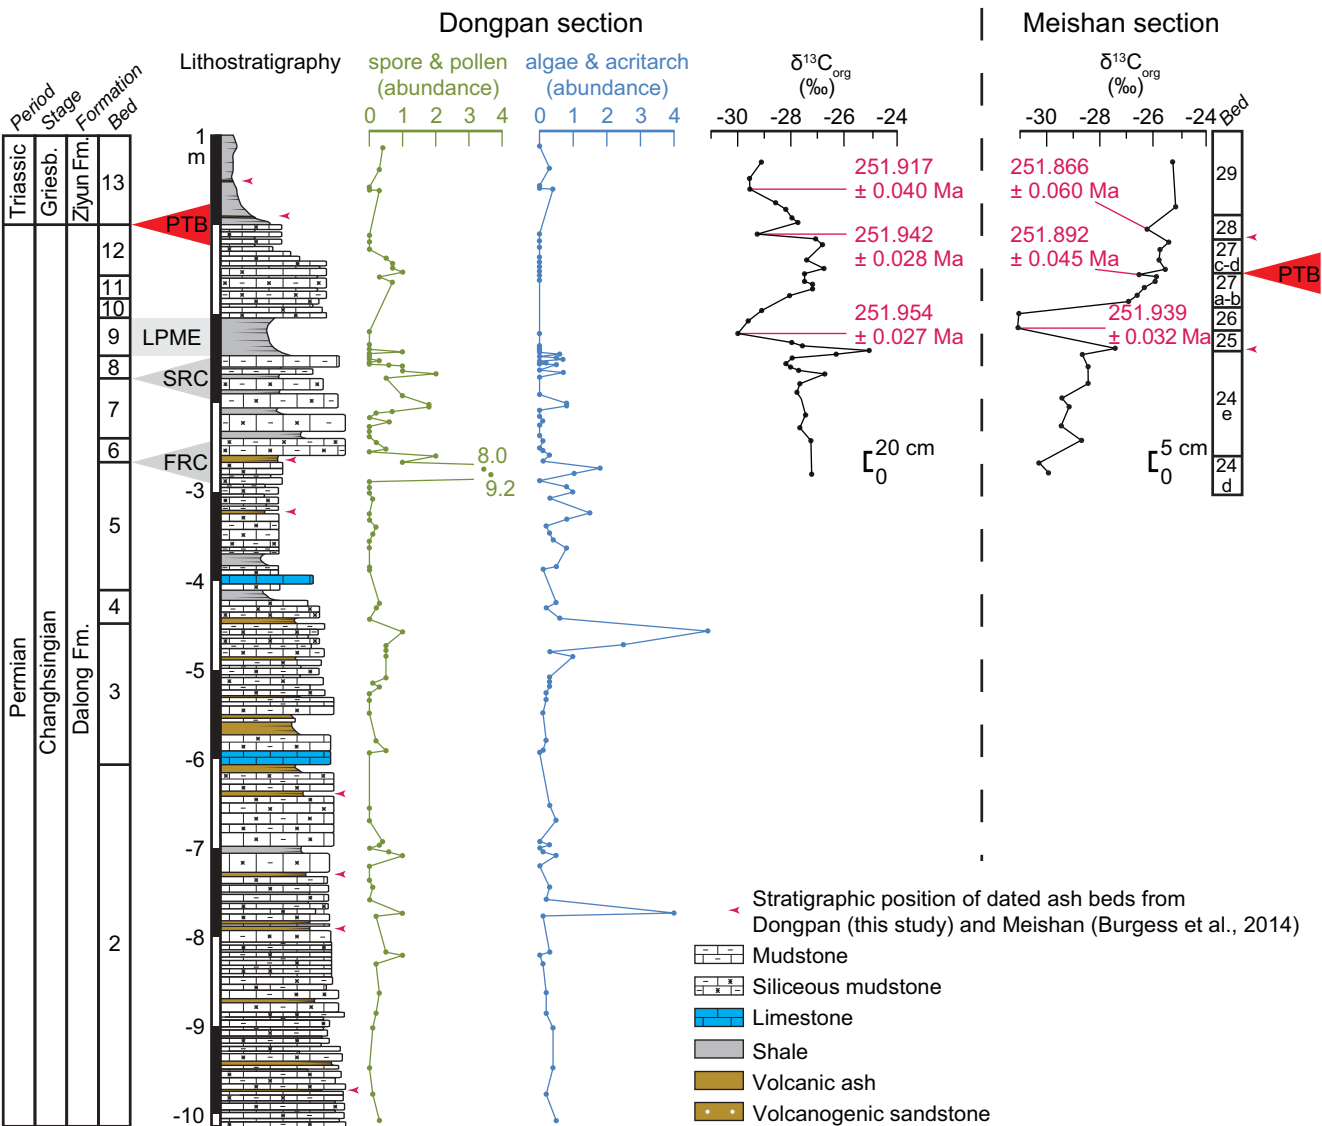

Fig. 7. Comparison of the organic carbon isotope chemostratigraphy of Dongpan (Zhang et al., 2006) with that of Meishan (Cao et al., 2002). Dates and their associated uncertainty for the negative carbon isotope excursions in both sections are revealed from the Bayesian Bchron age models of Dongpan and Meishan, respectively. Abundance of spores and pollen, as well as algae and acritarchs (i.e. spores/100 cm³ of soil) in Dongpan are from Shen et al. (2012). Stratigraphic positions of the First Radiolarian Crisis (FRC) and Second Radiolarian Crisis (SRC) (after Feng et al., 2007), the Latest Permian Extinction Event (LPME) in Dongpan and the Permian-Triassic Boundary (PTB) in both sections are indicated as well. Meishan section thickness is not to scale with Dongpan section.

Appendix A: Samples

The Dongpan section is situated at 22°16'11.80"N and 107°41'31.30"E, north-east of Liuqiao. The Penglaitan section is situated at 23°41'8.4"N and 109°18'21.0"E, east of Laibin.

Fig. A1. Studied volcanic ash beds (in black), radiolarian samples (in yellow), and their associated beds of the Changhsingian Dalong Fm. at the Dongpan section. Both pictures present the continuous Dongpan section, where the upper picture is stratigraphically above the lower one. The Permian-Triassic boundary (PTB) in Dongpan is marked by the lithological boundary between the Upper Permian Dalong Fm. and the Lower Triassic Ziyun Fm.

Fig. A2. Studied volcanic ash beds and volcaniclastic sandstones (in black), and conodont samples (in yellow) of the Penglaitan section. The Permian-Triassic boundary (PTB) is marked by the lithological boundary between the Upper Permian Dalong Fm. and the Lower Triassic Ziyun Fm.

738 Appendix B: U-Pb Zircon CA-ID-TIMS analysis

739 The samples were crushed and milled, and the powder was wet-sieved to remove the clay fraction. Heavy minerals were
740 isolated using methylene iodide. Single zircons were microscopically inspected and euhedral crystals were picked for
741 annealing at 900°C for ~48 h, followed by chemical abrasion with 40 % HF and trace HNO₃ in pressurized 200 µl Savillex
742 mini-capsules at 180°C for 18 h to minimize Pb loss effects (Mattinson, 2005). Since Ovtcharova et al. (2015) still revealed
743 apparent Pb loss in some zircon grains after 15 h of chemical abrasion, this study was optimized to the longer duration of 18
744 h to effectively overcome this obstacle.

745 After several washing steps with water, 6 N HCl, and 3 N HNO₃, single crystals were loaded in 200 µl Savillex capsules,
746 spiked with ~4 mg of the EARTHTIME ²⁰²Pb-²⁰⁵Pb-²³³U-²³⁵U tracer solution (hereafter referred to as ET2535; Condon et al.,
747 2015) and dissolved in ~70 µl 40 % HF and trace HNO₃ at 210°C for 48 h. After dissolution, samples were dried and re-
748 dissolved in 6 N HCl at 180°C for 12 h, dried down again and re-dissolved in 3 N HCl. U and Pb were collected in 3 ml
749 Savillex beakers after separation in a modified single 50 µl column anion exchange chemistry (Krogh, 1973) and dried down
750 with a drop of 0.05 M H₃PO₄. They were loaded on a single outgassed Re filament with a Si-gel emitter modified from
751 Gerstenberger and Haase (1997). Measurements of U and Pb isotopes were performed on a Thermo TRITON thermal
752 ionization mass spectrometer utilizing the ET2535 tracer calibration version 3.0 defined by Condon et al. (2015). Pb isotopes
753 were measured in dynamic mode on a MasCom secondary electron multiplier with a deadtime of 23 ns. Instrumental mass
754 fractionation was corrected using the fractionation factor derived from the measured ²⁰²Pb/²⁰⁵Pb ratio relative to a true value
755 of 0.99924. BaPO₂ interferences on mass 202 to 205 were corrected by determining ¹³⁸Ba³¹P¹⁶O¹⁶O concentration on mass
756 201 assuming natural abundance of ¹³⁸Ba of 71.7 %. No correction was applied for isobaric interference of Tl on mass 205
757 (natural abundance of ²⁰⁵Tl = 70.48 %, ²⁰³Tl = 29.52 %) since routine check of the Re filaments yielded negligible
758 concentrations on mass 203. U isotopes were measured in static mode on Faraday cups equipped with 10¹² Ω resistors as
759 UO₂⁺ and measured ratios were corrected for isobaric interferences of ²³³U¹⁸O¹⁶O on ²³⁵U¹⁶O¹⁶O using ¹⁸O/¹⁶O of 0.0020,
760 measured on large U500 loads, and for mass fractionation using the measured ²³³U/²³⁵U ratio relative to a value of 0.99506,
761 assuming a sample ²³⁸U/²³⁵U ratio of 137.818 ± 0.045 (2σ; Hiess et al., 2012). Raw data were statistical filtered by using the
762 Tripoli program, followed by data reduction including correct uncertainty propagation and online data visualization using U-
763 Pb_Redux software (Bowring et al., 2011; McLean et al., 2011). U-Pb ratios and dates were calculated relative to a tracer
764 ²³⁵U/²⁰⁵Pb ratio of 100.23 ± 0.046 % (2σ; Condon et al., 2015). All common Pb in the analyses was assumed to be procedural
765 blank yielding a long-term average ²⁰⁶Pb/²⁰⁴Pb ratio of 18.469 ± 0.458, ²⁰⁷Pb/²⁰⁴Pb ratio of 15.471 ± 0.320, ²⁰⁸Pb/²⁰⁴Pb ratio
766 of 38.011 ± 0.484 (uncertainties are given as 2σ) and an average of 0.52 pg during the course of this study.

809 Appendix C: Dongpan radiolarians

810 Feng et al. (2007) suggested that radiolarian faunas underwent two successive extinction phases in Dongpan. Their first
811 radiolarian crisis (FRC) occurs in bed 6 and their second radiolarian crisis (SRC) in bed 8 (see Appendix D). Hence, these
812 authors proposed that the decline of radiolarians preceded a late Permian mass extinction (LPME; see Appendix D) placed in
813 bed 9 on the basis of impoverished brachiopod, foraminifera and ostracod faunas (He et al., 2007; Yin et al., 2007) and of a
814 negative excursion of the $\delta^{13}\text{C}_{\text{org}}$ record (Zhang et al., 2006). Subsequently, Feng and Algeo (2014) published a new
815 radiolarian diversity curve showing the initiation of a protracted decline (“preliminary extinction”: PE) starting in the middle
816 part of bed 5. The second radiolarian crisis as initially recognized by Feng et al. (2007) is no longer visible in this
817 progressive diversity reduction at the species level.

818 As radiolarians are well known to be highly sensitive to selective preservation bias, the comparison of this apparent diversity
819 change with excess SiO_2 brings further insights. Shen et al. (2012) plotted excess SiO_2 along the Dongpan section but it is
820 unclear how much biogenic or volcanogenic silica respectively contributed to these values. Above bed 9, Shen et al. (2012)
821 also indicate absence of kaolinite in the clay fraction, suggesting that a lack of volcanoclastic input did contribute to the low
822 levels of excess SiO_2 . This drop of kaolinite and excess SiO_2 corresponds to the LPME of Feng et al. (2007) and to a lesser
823 degree to the “main extinction” (ME) of Feng and Algeo (2014), which they placed in bed 8. The coincidence between the
824 drop of excess SiO_2 and the LPME and/or the ME does not enable distinguishing a real extinction event of the radiolarians
825 from a selective preservation bias.

826 Feng and Algeo (2014) interpreted the onset of the radiolarian decline in bed 5 as being morphologically selective, with
827 long-spined species of the orders *Spumellaria* and *Entactinaria* preferentially going extinct relative to short-spined species.
828 However, such a statement requires precise investigation of the effects of diagenesis on a bed by bed basis, as post-
829 depositional dissolution can be extremely heterogeneous and guided by minor differences of available amount of SiO_2 in
830 each bed. The model proposed by Feng and Algeo (2014) for the evolution of radiolarian-bearing rocks calls upon changes
831 of oceanic redox conditions during the Permo-Triassic transition. This model is based on the assumption that Permian
832 radiolarians can be divided into three paleoecological assemblages based on proportions between four orders (*Entactinaria*,
833 *Spumellaria*, *Latentifistularia* and *Albaillellaria*), each restricted to shallow-, intermediate-, and deep-water environments.
834 Dongpan was one of the main examples used to support the claim that radiolarians were differentially affected around the
835 PTB events by an expansion of the oxygen minimum zone (OMZ). According to their scenario, deep-water taxa declined
836 earlier than shallow-water taxa as a result of an expansion of the OMZ. This ecological model of radiolarian stratification
837 with partial mutual taxonomic exclusion is only loosely supported by well-constrained Late Permian data worldwide and is
838 not supported when compared to the present-day planktonic mixing and diversity at any depth. Present-day studies on the
839 silica cycle (e.g., Tréguer and De La Rocha, 2013) show that biosiliceous deposits are strongly affected by post-depositional
840 dissolution at the water-sediment interface and during diagenesis. Last but not least, evidences supporting a rise of the OMZ
841 in Dongpan are lacking.

879 Appendix D: Penglaitan conodonts

880
 881 Fig. D1. Plate of Penglaitan conodonts ordered by taxon, sample number and conodont Unitary Associations zones after Brosse et
 882 al. (2016). 1) *Hindeodus inflatus* Nicoll, Metcalfe and Cheng-Yuan, PEN-23, UAZ3-UAZ5 (Griesbachian). The distal denticle is
 883 broader and slightly higher than the five posterior denticles. The denticles are evenly appressed along the carina, which is in
 884 contrast with holotype of *H. inflatus* Nicoll, Metcalfe and Cheng-Yuan. The height of the denticles decreases posteriorly,
 885 comparable to that of *H. postparvus* Kozur morphotype 1. In upper view, the carina is laterally compressed and rises directly from
 886 the expanded cup. The cup is symmetrical and much expanded. It opens from the distal denticle to the posterior end of the
 887 element. 2) *Hindeodus parvus* Kozur and Pjatakova (juvenile), PEN-23, UAZ3-UAZ5 (Griesbachian). The distal denticle is very
 888 high compared to the adjacent denticle. Only three denticles are following in this juvenile element. The blade rises from the round
 889 and symmetrical cup. 3) *Hindeodus ?praeparvus* Kozur, PEN-24. The distal denticle is broad and tall. Although most of the
 890 denticles of the carina are broken, the height of the carina seems to progressively decrease posteriorly. From his outline, this
 891 element resembles *H. typicalis* Sweet, with a progressive posterior inclination of the carina. The widely oppressed denticles seem to
 892 indicate a closer relation to *H. praeparvus* Kozur.
